#Using partitioned data, we observe a sharp decline in Cluster 3. Consequently, the size of multiple other clusters increased. The graphic shows that when the data is partitioned, the clusters appear to be more evenly distributed over the 12 clusters.

#4

#"The elementary public schools would like to choose a set of cereals to include in their daily cafeterias. Every day a different cereal is offered, but all cereals should support a healthy diet. For this goal, you are requested to find a cluster of "healthy cereals." Should the data be normalized? If not, how should they be used in the cluster analysis?"

#In this case, normalizing the data would not be appropriate. This is because the specific cereal sample under investigation determines how nutrition data from cereals should be scaled or normalized. Because of this, the data set that was collected might only contain cereals that are very high in sugar but low in iron, fiber, and other nutrients. It is impossible to estimate the nutritional value of cereal for a child once the data inside the sample set is scaled or normalized. An insensitive observer might conclude that a cereal with an iron score of 0.999 gives a child almost all of the iron they require, but it might actually be the best of the worst in the sample set, offering very little to no iron.

#Therefore, converting the data into a ratio to a child's daily recommended intake of calories, fiber, carbs, and other nutrients would be a better way to preprocess the data. By doing this, analysts would be able to evaluate clusters more intelligently and prevent a small number of significant variables from overriding distance calculations. When analyzing the clusters, an analyst may use the cluster averages to determine how much of a student's daily nutritional needs would come from XX cereal. This would allow the employees to choose "healthy" cereal clusters with greater knowledge.
